

Lecture 5. Data types and type classes

Functional Programming 2017/18

Alejandro Serrano

Goals

- ▶ Define your own data types
 - ▶ Simple, parametric and recursive
- ▶ Define your own type classes and instances

Chapter 8 (until 8.6) from Hutton's book

In the previous lectures...

... we have only used built-in types!

- ▶ Basic data types
 - ▶ Int, Bool, Char...
- ▶ Compound types parametrized by others
 - ▶ Some with a definite amount of elements, like tuples
 - ▶ Some with an unbound number of them, like lists

It's about time to define our own!

Direction

```
data Direction = North
                | South
                | East
                | West
```

- ▶ data declares a new **data type**
- ▶ The name of the type must start with **Uppercase**
- ▶ Then we have a number of *constructors* separated by |
 - ▶ Each of them also starting by uppercase
 - ▶ The same constructor cannot be used for different types
- ▶ Such a simple data type is called an *enumeration*

Building a list of directions

Each constructor defines a *value* of the data type

```
> :t North
North :: Direction
```

You can use `Direction` in the same way as `Bool` or `Int`

```
> :t [North, West]
[North, West] :: [Direction]
> :t (North, True)
(North, True) :: (Direction, Bool)
```

Pattern matching over directions

To define a function, you proceed as usual:

1. Define the type

```
directionName :: Direction -> String
```

2. Enumerate the cases

- ▶ The cases are each of the constructors

```
directionName North = _
```

```
directionName South = _
```

```
directionName East = _
```

```
directionName West = _
```

Pattern matching over directions

3. Define each of the cases

```
directionName North = "N"
```

```
directionName South = "S"
```

```
directionName East = "E"
```

```
directionName West = "W"
```

```
> map directionName [North, West]  
["N", "W"]
```

Built-in types are just data types

- ▶ Bool is a simple enumeration

```
data Bool = False | True
```

- ▶ Int and Char can be thought as very long enumerations

```
data Int = ... | -1 | 0 | 1 | 2 | ...
```

```
data Char = ... | 'A' | 'B' | ...
```

- ▶ The compiler treats these in a special way

Points

Data types may store information within them

```
data Point = Pt Float Float
```

- ▶ The name of the constructor is followed by the list of types of each argument
- ▶ Constructor and type names may overlap

```
data Point = Point Float Float
```

Using points

- ▶ To create a point, we use the name of the constructor followed by the value of each argument

```
> :t Pt 2.0 3.0
Pt 2.0 3.0 :: Point
```

- ▶ To pattern match, we use the name of the constructor and further matches over the arguments

```
norm :: Point -> Float
norm (Pt x y) = sqrt (x*x + y*y)
```

- ▶ Do not forget the parentheses!

```
> norm Pt x y = x * x + y * y
```

```
<interactive>:2:6: error:
```

- The constructor 'Pt' should have 2 arguments, but has been given none

Constructors are functions

Each constructor in a data type is a function which build a value of that type given enough arguments

```
> :t North
```

```
North :: Direction -- No arguments
```

```
> :t Pt
```

```
Pt :: Float -> Float -> Point -- 2 arguments
```

They can be arguments or results of higher-order functions

```
zipPoint :: [Float] -> [Float] -> [Point]
zipPoint xs ys = map (uncurry Pt) (zip xs ys)
                -- = [Pt x y | (x, y) <- zip xs ys]
```

Shapes

A data type may have zero or more *constructors*, each of them holding zero or more *arguments*

```
data Shape = Rectangle Point Float Float
           | Circle     Point Float
           | Triangle  Point Point Point
```

We call these **algebraic data types**, or **ADTs**

Pattern matching over shapes

Each case starts with a constructor – in uppercase – and matches the arguments

```
area :: Shape -> Float
area (Rectangle _ w h) = w * h
area (Circle _ r)      = pi * r * r
area (Triangle x y z) = sqrt (s*(s-a)*(s-b)*(s-c))
                        -- Heron's formula

  where a = distance x y
        b = distance y z
        c = distance x z
        s = (a + b + c) / 2
```

```
distance (Pt u1 u2) (Pt v1 v2)
  = sqrt ((u1-v1)*(u1-v1)+(u2-v2)*(u2-v2))
```

ADTs versus object-oriented classes

```
abstract class Shape {  
    abstract float area();  
}  
class Rectangle : Shape {  
    public Point corner;  
    public float width, height;  
    public float area() { return width * height; }  
}  
  
// More for Circle and Triangle
```

- ▶ There is no *inheritance* involved in ADTs
- ▶ Constructors in an ADT are *closed*, but you can always add *new subclasses* in a OO setting
- ▶ Classes bundle *methods*, functions for ADTs are defined *outside* the data type

Nominal versus structural typing

```
data Point = Pt Float Float
```

```
data Vector = Vec Float Float
```

- ▶ These types are *structurally* equal
 - ▶ They have the same number of constructors with the same number and type of arguments
- ▶ But for the Haskell compiler, they are unrelated
 - ▶ You cannot use one in place of the other
 - ▶ This is called *nominal* typing

```
> :t norm
```

```
norm :: Vector -> Float
```

```
> norm (Pt 2.0 3.0)
```

```
Couldn't match 'Vector' with 'Point'
```

Lists and trees of numbers

Data types may refer to themselves

- ▶ They are called **recursive** data types

```
data ListOfNumbers
```

```
= EmptyList | OneMore Int ListOfNumbers
```

```
data TreeOfNumbers
```

```
= EmptyTree | Node Int TreeOfNumbers TreeOfNumbers
```

Cooking elemList

1. Define the type

```
elemList :: Int -> ListOfNumbers -> Bool
```

2. Enumerate the cases

- ▶ One equation per constructor

```
elemList x EmptyList      = _  
elemList x (OneMore y ys) = _
```

3. Define the cases

```
elemList x EmptyList = False  
elemList x (OneMore y ys)  
  | x == y      = True  
  | otherwise   = elemList x ys
```

Cooking elemTree

1. Define the type

```
elemTree :: Int -> TreeOfNumbers -> Bool
```

2. Enumerate the cases

- ▶ Each constructor needs to come with as many variables as arguments in its definition

```
elemList x EmptyTree      = _  
elemList x (Node y rs ls) = _
```

3. Define the simple (base) cases

```
elemList x EmptyTree = False
```

Cooking elemTree

4. Define the other (recursive) cases

- ▶ Each recursive appearance of the data type as an argument usually leads to a recursive call in the function

```
elemList x (Node y rs ls)
  | x == y      = True
  | otherwise   = elemList x rs || elemList x ls
```

-- Or simpler

```
elemList x (Node y rs ls)
  = x == y || elemList x rs || elemList x ls
```

Cooking treeToList

1. Define the type

```
treeToList :: TreeOfNumbers -> ListOfNumbers
```

2. Enumerate the cases

```
treeToList EmptyTree      = _  
treeToList (Node x ls rs) = _
```

3. Define the simple (base) cases

```
treeToList EmptyTree      = EmptyList
```

Cooking treeToList

4. Define the other (recursive) cases

```
treeToList (Node x ls rs)
  = OneMore x (concatList ls' rs')
  where ls' = treeToList ls
        rs' = treeToList rs
```

-- Left as an exercise to the audience

```
concatList :: ListOfNumbers -> ListOfNumbers
           -> ListOfNumbers
concatList xs = _
```

Polymorphic data types

We have seen examples of types which are parametric

- ▶ Lists like `[Int]`, `[Bool]`, `[TreeOfNumbers]`...
- ▶ Tuples `(A, B)`, `(A, B, C)` and so on

Functions over these data types can be polymorphic

- ▶ They work regardless of the parameter of the type

```
(++) :: [a] -> [a] -> [a]
```

```
zip  :: [a] -> [b] -> [(a, b)]
```

Optional values

Maybe T represents a value of type T which might be absent

```
data Maybe a = Nothing
              | Just a
```

- ▶ In the declaration of a polymorphic data type, the name `Maybe` is followed by one or more type variables
 - ▶ Type *variables* start with a lowercase letter
- ▶ The constructors may refer to the type variables in their arguments
 - ▶ In this case, `Just` holds a value of type `a`

Optional values

```
> :t Just True
```

```
Maybe Bool
```

```
> :t Nothing
```

```
Maybe a
```

Note that `Nothing` has a polymorphic type, since there is no information to fix what `a` is

Cooking find

`find p xs` finds the first element in `xs` which satisfies `p`

- ▶ Such an element may not exist
 - ▶ Think of `find even [1,3]`, or `find even []`
- ▶ Other languages resort to `null` or magic `-1` values
- ▶ Haskell always marks a possible absence using `Maybe`

1. Define the type

```
find :: (a -> Bool) -> [a] -> Maybe a
```

2. Enumerate the cases

```
find p []      = _  
find p (x:xs) = _
```

Cooking find

3. Define the simple (base) cases

```
find _ [] = Nothing
```

4. Define the other (recursive) cases

```
find p (x:xs) | p x      = Just x  
              | otherwise = find p xs
```

elem in terms of find

Let me define a small utility function

```
isJust :: Maybe a -> Bool
isJust Nothing = False
isJust (Just _) = True
```

Then we can define elem as a composition of other functions

```
elem :: Eq a => a -> [a] -> Bool
elem x = isJust . find (== x)
```

Trees for any type

We can generalize our `TreeOfNumbers` data type

- ▶ This is a polymorphic and recursive data type
- ▶ Mind the parentheses around the arguments

```
data Tree a = Leaf
            | Node a (Tree a) (Tree a)
```

More recipes with trees

Next lecture

Many more operations over trees!

- ▶ Including *search* trees

Type classes

Overloaded types

From previous lectures...

Some functions work uniformly for all types

```
reverse :: [a] -> [a]
```

But others require the type to satisfy a constraint

```
elem :: Eq a => a -> [a] -> Bool
```

```
(+) :: Num a => a -> a -> a
```

- ▶ Eq and Num are called **(type) classes**
- ▶ Each type which satisfies the constraint is an **instance**
 - ▶ Int is an instance of class Eq
- ▶ **Warning!** Terminology conflict with other languages

Class definition

```
class Eq a where
  (==) :: a -> a -> Bool
  (/=) :: a -> a -> Bool
```

- ▶ The name of the type class starts with **Uppercase**
- ▶ We declare a type variable – a in this case – to stand for the overloaded type in the rest of the declaration
- ▶ Each type class defines one or more **methods** which must be implemented for each instance
 - ▶ We do *not* write the constraint in the methods

Missing instances

```
> Pt 2.0 3.0 == Pt 2.0 3.0
```

```
<interactive>:2:1: error:
```

- No instance for (Eq Point)
arising from a use of '=='
- ▶ You have to give the instance declaration for your own data types, even for built-in type classes
 - ▶ In some cases, the compiler can write them for you

Instance declarations

```
instance Eq Point where
```

```
Pt x y == Pt u v = x == u && y == v
```

```
Pt x y /= Pt u v = x /= u || y /= v
```

- ▶ Almost like the class declaration, except that
 - ▶ The type variable is substituted by a real type
 - ▶ Instead of method types, you give the implementation

```
> Pt 2.0 3.0 == Pt 2.0 3.0
```

```
True
```

Instance signatures

It is useful to write the specialized type for the instance in the declaration

```
instance Eq Point where
  (==) :: Point -> Point -> Bool
  Pt x y == Pt u v = x == u && y == v
  (/=) :: Point -> Point -> Bool
  Pt x y /= Pt u v = x /= u || y /= v
```

The Haskell standard does not allow this

- ▶ But you can do this if you write at the top of the file

```
{-# language InstanceSigs #-}
```

Recursive instances

Type class instances for polymorphic types may depend on their parameters

- ▶ For example, equality of lists, tuples, and trees
- ▶ These requisites are listed in front of the declaration

```
instance Eq a => Eq [a] where
  [] == [] = True
  [] == _ = False
  _ == [] = False
  (x:xs) == (y:ys) = x == y && xs == ys
```

```
instance (Eq a, Eq b) => Eq (a, b) where
  (x, y) == (u, v) = x == u && y == v
```

Overlapping instances

Imagine that I want tuples of `Ints` to work slightly different

```
instance Eq (Int, Int) where
  (x, y) == (u, v) = x * v == y * u
```

You *cannot* do this! This instance **overlaps** with the other one given for generic tuples

Superclasses

A class might demand that other class is implemented

- ▶ We say that such a class has a **superclass**
- ▶ For example, any class with an ordering – `Ord` – has to implement equality – `Eq`

```
class Eq a => Ord a where
  (<), (>), (<=), (>=) :: a -> a -> Bool
  min, max           :: a -> a -> a
```

```
instance (Ord a, Ord b) => Ord (a, b) where
  (x, y) < (u, v) | x == u    = y < v
                | otherwise = x < u
```

The meanings of =>

- ▶ In a type, it constraints a polymorphic function
`elem :: Eq a => a -> [a] -> Bool`
- ▶ In a class declaration, it introduces a superclass
`class Eq a => Ord a where ...`
 - ▶ All instances of `Ord` must be instances of `Eq`
- ▶ In an instance declaration, it defines a requisite
`instance Eq a => Eq [a] where ...`
 - ▶ A list `[T]` supports equality only if `T` supports it

Before `=>` you write an *assumption* or *precondition*

Default definitions

We could also write the following instance `Eq Point`

```
instance Eq Pt where
  Pt ... == Pt ... = _ -- as before
  p /= q = not (p == q)
```

In fact, this definition of `(/=)` works for *any* type

- ▶ You can include a *default* definition in `Eq`
- ▶ If an instance does not have an explicit definition for that method, the default one is used

```
class Eq a where
  (==), (/=) :: a -> a -> Bool
  x /= y = not (x == y)
```

Default definitions

- ▶ You could have also defined (`/=`) *outside* of the class

```
(/=) :: Eq a => a -> a -> Bool  
x /= y = not (x == y)
```

- ▶ This definition cannot be overridden in each instance
- ▶ Why do we prefer (`/=`) to live in the class?
 - ▶ Performance! For some data types it is cheaper to check for disequality than for equality

Automatic derivation

- ▶ Writing equality checks is boring
 - ▶ Go around all constructors and arguments
- ▶ Writing order checks is even more boring
- ▶ Turning something into a string is also boring

Let the compiler work for you!

```
data Point = Pt Float Float
           deriving (Eq, Ord, Show)
```

Historical note: many of the advances in automatic derivation of type classes were done here at UU

Define your own data types!

Data types in Haskell are simple and cheap to define

- ▶ Introduce one per concept in your program

-- the following definition

```
data Status = Stopped | Running
```

```
data Process = Process ... Status ...
```

-- is better than

```
data Process = Process ... Bool ...
```

-- what does 'True' represent here?

- ▶ Use type classes to share commonalities

Example: scalable things

Both shapes and vector have a notion of *scaling*

- ▶ Scale the size or scale the norm

```
class Scalable s where
  scale :: Float -> s -> s
```

Example: scalable things

Both shapes and vector have a notion of *scaling*

- ▶ Scale the size or scale the norm

```
class Scalable s where
  scale :: Float -> s -> s
```

```
instance Scalable Vector where
  scale s v@(Vec x y) = Vec (n*x) (n*y)
    where n = s / norm v
```

```
instance Scalable Shape where
  scale s (Rectangle p w h) = Rectangle p (s*w) (s*h)
  scale s (Circle p r)     = Circle p (s*r)
  scale s (Triangle x y z) = ... -- This is hard
```

Generic functions for scalable things

- ▶ Some functions now work over any scalable thing

```
double :: Scalable s => s -> s  
double = scale 2.0
```

- ▶ We may generic instances for composed scalables

```
instance Scalable s => Scalable [s] where  
  scale s = map (scale s)
```

Overloaded syntax

Numeric constants' weird type

What is going on?

```
> :t 3  
3 :: Num t => t
```

Numeric constants can be turned into any `Num` type

```
> 3 :: Integer  
3  
> 3 :: Float  
3.0  
> 3 :: Rational -- Type of fractions  
3 % 1           -- Numerator % Denominator
```

Range syntax

The range syntax `[n .. m]` is a shorthand for

```
enumFromTo n m
```

`enumFromTo` lives in the class `Enum`

- ▶ `Bool` and `Char` are instances, among others

```
> ['a' .. 'z']
```

```
"abcdefghijklmnopqrstuvwxy"
```

More range syntax

```
enumFrom      :: a -> [a]
```

```
enumFromThenTo :: a -> a -> a -> [a]
```

- ▶ `enumFrom` does not specify a bound for the range
 - ▶ The list is possibly infinite

```
> take 5 [1 ..]  
[1,2,3,4,5]
```

- ▶ `enumFromThenTo` generates a list where each pair of adjacent elements has the same distance

```
> [1.0, 1.2 .. 2.0]  
[1.0,1.2,1.4,1.5999999999999999,  
 1.7999999999999998,1.9999999999999998]
```

Deriving Enum

enumFromTo can be automatically derived for enumerations

- ▶ Data types without data in their constructors

```
data Direction = North | South | East | West
               deriving (Eq, Ord, Show, Enum)
```

```
> [South .. West]
[South, East, West]
```
